Abstract

The ispell family of spellcheckers is perhaps the single most widely ported and deployed open-source language tool. Here we describe how the SzőSzablya ‘WordSword’ project leverages ispell’s Hungarian descendant, HunSpell, to create a whole set of related tools that tackle a wide range of low-level NLP-related tasks such as character set normalization, language detection, spellchecking, stemming, and morphological analysis.

1. Introduction

Over the years, open source unix distributions have become the definitive repositories of tried and tested algorithms. In the area of natural language processing, wellformedness of words is typically checked by the ispell family of spellcheckers that goes back to Gorin’s spell program (see Peterson 1980), a spellchecker for English written in PDP-10 assembly. Since at the core of spellchecking is a method for accurate word recognition, it is an ideal platform both for reaching “down” toward language identification and for reaching “up” toward stemming and morphological analysis. The SzőSzablya ‘WordSword’ project at the Budapest Institute of Technology leverages the ispell methods with the goal to extend them to a general toolkit applicable to various low-level NLP-related problems other than spell-checking such as language detection, character set normalization, stemming, and morphological analysis.1

The algorithms described here go back to the roots of the spell -- ispell -- International Ispell -- MySpell -- HunSpell development. The linguistic theory implicit in much of the work has an even deeper historical lineage, going back at least to the Bloomfield–Bloch–Harris development of structuralist morphology via Antal’s (1961) work on Hungarian. Despite our indebtedness to these traditions, this paper does not attempt to faithfully trace the twists and turns of the actual history of ideas, rather it offers only a rational reconstruction of the underlying logic.

A high performance spellchecker can easily be leveraged for language identification, and we have relied heavily on HunSpell both for this purpose and for overall quality improvement in creating a gigaword Hungarian corpus (see the main conference paper Halácsy et al 2004). Orthographic form and, by implication, spellchecking technology, remains the Archimedian point of natural language text processing both “downward” and “upward”. Here we will concentrate entirely on the “upward” developments leading to HunStem, a full featured industrial strength stemmer that supports large-scale Information Retrieval applications, and eventually to HunMorph, an open source morphological analyzer.2 Though the names HunSpell and HunStem suggest Hungarian orientation, in the spirit of ispell our project keeps the technology perfectly separated from lexical resources, making the tools are directly applicable to other languages provided that lexical databases are available. Resources for the applications can be compiled from a single lexical database and morphological grammar with the help of the HunLex resource compilation tool.

The paper is structured as follows. Section 2 provides a brief introduction to the morphological analysis/generation problem from the perspective of spellchecking, and discusses how the affix–flag mechanism introduced to ispell by Ackerman in 1978 has been modified to deal with multi-step affix stripping to attack the problem of languages with rich morphology. Section 3 describes how, by enabling multiple analyses, treatment of homonyms, and flexible output of stem information, the general framework of HunSpell has been extended to support stemming. In the concluding Section 4 we describe how the codebase can be leveraged even further, to support detailed morphological analysis.

2. The morphological OOV problem

The simplest spellchecker, both conceptually and in terms of optimal runtime performance, is a list of all correctly spelled words. Acceleration and error correction techniques based on hashes, tries, and finite automata have been extensively studied, and the implementor can choose from a variety of open source versions of these techniques. Therefore the spellchecking problem could be reduced, at least conceptually, to the problem of listing the correct words, whereby errors of the spellchecker are reduced to out of vocabulary (OOV) errors. A certain amount of OOV error is inevitable: new words are coined all the time, and the supply of exotic technical terms and proper names is inexhaustible. But as a practical matter, developers encounter

1 Aversano et al 2002 is the only related attempt we know of.

2 For further upward developments such as named entity extraction, parsing, or semantic analysis, orthography gradually loses its grip over the problem domain, but none of these higher-level developments are feasible without tackling the low-level issues first.

3 For the history of ispell/MySpell, see the man pages.
OOV errors early on from another source: morphologically complex words such as compounds and affixed forms.

The ability to reverse compounding and affixation has a very direct payoff in terms of reducing memory footprint, and it is no surprise that affix stripping ability was built into ispell early on. Initially, (i)spell only used heuristics for affix stripping before looking up hypothesized stems in a base dictionary. This was substantially improved by the introduction of switches (in linguistic terms these would be called private lexical features) that license particular affix rules and thus help eliminate spurious hits resulting from the unreliable heuristic method.

In 1988 Geoff Kuenning extended affix flags to license sets of affix rules. In this table-driven approach, affix flags are interpreted as lexical features that indicate morphological subparadigm membership. This method of affix compression allowed for less redundant storage and efficient run-time checking of a great number of affixes, thereby enabling ispell to tackle languages with more complex morphological systems than English. After major modifications of the code, the first multi-lingual version of ispell was released in 1988.

Ispell can also handle compounds and there is even the possibility of specifying lexical restrictions on compounding, also implemented as switches in the base dictionary. For some languages, a rich set of compound constructions allow for productive extensions of the base vocabulary, and this feature is indispensable in mitigating the OOV problem. Language-specific word-lists and affix rules for ispell, with added switch information as necessary, have been compiled for over 50 languages so far. Our development started with providing open source spell-checking for Hungarian. Our spellchecker, HunSpell is based on MySpell, a portable and thread-safe C++ library reimplementation of ispell written by Kevin Hendricks. We chose MySpell as the core engine for our development both because of its implementational virtues, and because the non-restrictive BSD license significantly enhances its potential in open source development and large-scale code reuse.

The lexical resources of MySpell (the affix file and the dictionary file) are processed at runtime, which makes them directly portable across various platforms. A line in the affix file represents an affix rule from a generation point of view. It specifies a regexp-like pattern which is matched against the beginning or end of the base for prefix and suffix respectively, a string to strip from, and the actual affix string to append to the input base. A special indexing technique, the Dömölki algorithm is used in checking affixation conditions (Dömölki 1967) to pick applicable affix rules in parsing. A pseudo-stem is hypothesized by reverse application of the affix rule (i.e., stripping the append string and appending the strip string) which is looked up in the dictionary. A line in the dictionary file represents a lexical entry, i.e., a base form associated with a set of affix flags. If the hypothesized base is found in the dictionary after the application of an affix rule, in the last step it is checked whether its flags contain the one the affix rule is assigned to.

Though the ispell algorithm performs affix stripping and lexical lookup very efficiently, the implementation does not scale well to languages with rich morphology. ispell lexical resources actually exist for some languages with famously rich productive morphology such as Estonian, Finnish, and Hungarian, but it is suggestive that the latter two languages use enhancements over MySpell in their native OpenOffice.org releases for spellchecking. The Hungarian version uses our development, the HunSpell library which incorporates various spell-checking features specifically needed to correctly handle Hungarian orthography – we turn to these now.

So far we spoke of affixes only in the sense of edge-aligned substrings (prefixes and suffixes), but in languages with complicated combinatorial morphology affix rules might stand for intricate clusters of affix morphemes (the sense of affix used in linguistics). Such morphotactic complexity, a hallmark of rich productive morphology, often makes it difficult to list all legitimate affix combinations, let alone produce them automatically: the sheer size and redundancy of precompiled morphologies make modifications very difficult and debugging nearly impossible. Maintaining these resources without a principled framework for off-line resource compilation is virtually a hopeless enterprise, witness magyarispell, the Hungarian MySpell resource which resorts to a clever (from a maintainability perspective, way too clever) mix of shell scripts, m4 macros, and hand-written pieces of MySpell resources.

To remedy this problem we devised an off-line resource compilation tool which given a central lexical database and a morphological grammar can create resources for the applications according to a wide range of configurable parameters. HunLex is a language-independent pre-processing framework for a rule-based description of morphology (details about grammar specifications and configuration options of HunLex would go beyond this paper).

To handle all the productive inflections magyarispell requires about 20 thousand combined entries. Extending this database to incorporate productive derivational morphology would mean an order of magnitude increase, as full derivation and inflection can yield ca. $10^3-10^9$ word forms from a single nominal base. Taking orthogonal prefix combinations into account would result in another order of magnitude increase, leading to file sizes unacceptable in a practical system.

Using the magyarispell resources, on the 5 million word types of the Szőszabloya web corpus (Halácsy et al. 2004), HunSpell’s recognition performance is about 96% (OOV is 4%). Taking word frequencies into account OOV is only 0.2% (i.e. recall is near perfect, 99.8%). While these figures are quite reassuring for the central use case of flagging spelling errors, in order to offer high quality replacements we can’t ignore rare but perfectly well-formed complex forms. Decreased OOV is also indispensable for wide-coverage morphological analysis and Information Re-

---

4MySpell has been incorporated into OpenOffice.org’s office suite, where it replaces the third-party libraries licensed earlier.

trieval applications.

To solve the morphological OOV problem HunSpell now incorporates a multi-step sequential affix-stripping algorithm. After stripping an affix-cluster in step $i$, the resulting pseudo-stem can be stripped of affix-clusters in step $i + 1$. Legitimate strippings can be checked in exactly the same way as for valid online base+affix combinations, and are encoded with the help of switches in the resource file. Implementing this only required a minor extension of the data structure coding affix entries and a recursive call for stripping. Currently this scheme is implemented for two steps (plus lexical lookup) for suffixation plus one for prefixation, but can easily be extended to a fully recursive method. From the structuralist perspective, the clustering step implements a kind of position class analysis (Nida 1949, Harris 1951), and from a generative perspective it implements a simplified version of lexical phonology and morphology (Kiparsky 1982). Besides the well-known theoretical justifications for this style of analysis, there is a compelling practical justification in that the size of the affix table shrinks substantially: with our particular setting for Hungarian, the multi-step resource is the square root of the single-step one in size. HunLex can be configured to cluster any or no set of affixes together on various levels, and therefore resources can be optimized on either speed (toward one-level) or memory use (affix-by-affix stripping).

Prefix–suffix dependencies An interesting side-effect of multi-step stripping is that the appropriate treatment of circumfixes now comes for free. For instance, in Hungarian, superlatives are formed with simultaneous prefixation of leg- and suffixation of -bb to the adjective base. A problem with the one-level architecture is that there is no way to render lexical licensing of particular prefixes and suffixes interdependent, and therefore incorrect forms are recognized as valid, i.e. *legvén = leg + vén ‘old’. Until the introduction of clusters a special treatment of the superlative had to be hardwired in the earlier HunSpell code. This may have been legitimate for a single case, but in fact prefix–suffix dependences are ubiquitous in category-changing derivational patterns (cf. English payable, non-payable but *non-pay or drinkable, undrinkable but *un-drink). In simple words, here, the prefix un- is legitimate only if the base drink is suffixed with -able. If both these patterns are handled by on-line affix rules and affix rules are checked against the base only, there is no way to express this dependency and the system will necessarily over- or undergenerate.

Compounds Allowing free compounding yields decrease in precision of recognition, not to mention stemming and morphological analysis. Although lexical switches are introduced to license compounding of bases by ispell, this proves not to be restrictive enough. This has been improved upon with the introduction of direction-sensitive compounding, i.e., lexical features can specify separately whether a base can occur as leftmost or rightmost constituent in compounds. This, however, is still insufficient to handle the intricate patterns of compounding, not to mention idiosyncratic (and language specific) norms of hyphenation.

The MySpell algorithm currently allows any affixed form of words which are lexically marked as potential members of compounds. Hunspell improved upon this, and its recursive compound checking rules makes it possible to implement the intricate spelling conventions of Hungarian compounds. This solution is still not ideal, however, and will be replaced by a pattern-based compound-checking algorithm which is closely integrated with input buffer tokenization. Patterns describing compounds come as a separate input resource that can refer to high-level properties of constituent parts (e.g. the number of syllables, affix flags, and containment of hyphens). The patterns are matched against potential segmentations of compounds to assess well-formedness.

3. Stemming and morphological analysis

So far, we only touched upon general issues pertaining to the recognition of morphologically complex forms in highly inflecting languages. It is easy to realize, however, that the same general architecture can easily be extended to more sophisticated analysis tools for morphological processing. A straightforward extension we implemented allowed Hunspell to output lexical stems, thereby turning it into a simplistic stemmer.

Practically, stemmers are used as a recall enhancing device for Information Retrieval systems (Kraaij and Pohlmann 1996, Hull 1996). Stemmers ideally conflate semantically related wordforms, so indexing words by their stems effectively expands the relevant search space. The relevance of this ubiquitous NLP technique is greater for languages with rich (inflectional) morphology and/or relatively smaller corpus. Stemmers based on various approximate heuristics (Porter 1980, Paice 1994) are already quite robust and ones based on corpus statistics can be totally language independent (Xu and Croft 1998). However, these methods very often produce nonwords the human interpreter of which is difficult, which makes debugging of false confessions hard. Therefore, once linguistic resources are available, stemming based on linguistically motivated morphological analysis is beneficial at least from a maintainability perspective.

To turn HunSpell into HunStem, a fully functional grammar-based stemmer, we had to address several issues beyond the trivial provision for stem output. First, for the recognition problem relevant in word-based spellchecking, no multiple analyses are needed, so the processing of a word can terminate with the first successful analysis. For any stemmer of practical use, this is insufficient, and coming up with alternative stems for morphologically ambiguous forms is a definitive requirement. This has been implemented and HunStem now performs exhaustive search for analyses and outputs all potential stems.

Second, for stemming it is desirable that homonymous stems be disambiguated if affixation provides the necessary cues. This is usually the case with ambiguous stems belonging to different paradigms or categories like Hun-
The next logical step is a full-fledged morphological analysis tool for Hungarian. Many of the prerequisites of morphological analysis, in particular the flexibility to define the set of morphemes left unanalyzed at compile time, were fulfilled in the course of the HunStem development, and a pilot version of HunMorph is already operational. In principle, HunLex method of dictionary resource precompilation is applicable even to Kimmo-style systems, where the inner loop is based on finite state transduction rather than the generic string manipulation techniques used in ispell, but in the absence of a non-restrictive license open source two-level compiler we are not in a position to pursue this line of research.
